Size Composition in Fish Communities

OSPAR Convention

The Convention for the Protection of the Marine Environment of the North-East Atlantic (the “OSPAR Convention”) was opened for signature at the Ministerial Meeting of the former Oslo and Paris Commissions in Paris on 22 September 1992. The Convention entered into force on 25 March 1998. The Contracting Parties are Belgium, Denmark, the European Union, Finland, France, Germany, Iceland, Ireland, Luxembourg, the Netherlands, Norway, Portugal, Spain, Sweden, Switzerland and the United Kingdom.

Convention OSPAR

La Convention pour la protection du milieu marin de l’Atlantique du Nord-Est, dite Convention OSPAR, a été ouverte à la signature à la réunion ministérielle des anciennes Commissions d’Oslo et de Paris, à Paris le 22 septembre 1992. La Convention est entrée en vigueur le 25 mars 1998. Les Parties contractantes sont l’Allemagne, la Belgique, le Danemark, l’Espagne, la Finlande, la France, l’Irlande, l’Islande, le Luxembourg, la Norvège, les Pays-Bas, le Portugal, le Royaume- Uni de Grande Bretagne et d’Irlande du Nord, la Suède, la Suisse et l’Union européenne

Key Message

The Typical Length indicator measures the size-structure of fish communities and it decreases under high fishing pressure. The indicator is low, compared to the 1980s, in the Greater North Sea and Celtic Seas Regions, but it has increased across large parts of the central Celtic Seas and the northern Bay of Biscay.

Background (brief)

OSPAR's strategic objective with respect to biodiversity and ecosystems is to protect and conserve marine biodiversity, ecosystems and their services to achieve good status of species and habitats, and thereby maintain and strengthen ecosystem resilience.

The Typical Length indicator is one of multiple food web indicators currently used by OSPAR to assess fish communities. It represents the average length of fish (demersal bony fish and elasmobranchs) and provides information on the size structure within communities. The indicator is calculated using catch data from species sampled by scientific surveys. Communities are represented by habitat-based feeding assemblages (groups of fish): namely, demersal assemblages (i.e., species living on or near the sea floor) within ecological subdivisions. Pelagic assemblages of fish (i.e., species living in the water column) are captured elsewhere within indicators of mean trophic level and indicators of the biomass of feeding guilds.

Fishing mortality constrains the age structure of fish populations, reducing the proportion of larger individuals (**Figure 1**). A gradual, steady decline in Typical Length is expected in response to high fishing pressure and fishing at Maximum Sustainable Yield is expected to lead to a recovery in the indicator (Spence *et al.*, 2021). This is because the size structure of the fish assemblage integrates the impacts of fishing pressure over long periods of time. Model simulations demonstrate that in food webs where predator-prey interactions dominate over other interactions, large species at high trophic levels (the position of the species within the food web) are highly sensitive to loss of diversity at lower trophic levels. As large-bodied piscivores decline, smaller forage fish suffer reduced predation mortality further decreasing Typical Length indicating adversely impacted food webs.

Background (extended)

The distribution of biomass over body size (size spectra; Kerr and Dickie, 2001) is an emergent property of food webs, therefore size-based metrics that are sensitive and specific to pressures can be used as indicators of food-web structure. Jennings *et al.*, (2007) found that body size was related to trophic level in fish in the North Sea at the community level (see also Reum *et al.*, 2015). Barnes *et al.*, (2010) demonstrated the relationship between fish size and trophic transfer efficiency. Riede *et al.*, (2011) demonstrated that log-mean body size was significantly related to trophic level in marine invertebrates, and ectotherm and endotherm vertebrates using data on multiple ecosystems. Model simulations (Rossberg *et al.*, 2008) have demonstrated that in food webs where trophic interactions dominate over other interactions, large species at high trophic levels are highly sensitive to loss of diversity at lower trophic levels (ICES, 2014a).

Fishing is a size-selective process therefore fish body size decreases during overexploitation (Boudreau and Dickie, 1992). A gradual, steady decline in Typical Length is expected in response to high fishing pressure because the size structure of the community integrates the impacts of fishing pressure over long periods of time (Rossberg, 2012; Fung *et al.*, 2013). Processes related to rising sea temperature also serve to reduce body size of fish (Daufresne *et al.*, 2009; Gibert and DeLong, 2014). The indicator can respond to pressures on the marine environment that impact individual fish directly (entanglement activities) or indirectly (through change in their seabed or pelagic habitat, primary production and food-web interactions).

The indicator is aggregated at the survey level within each region assessed and complemented by subdivisional analyses at a scale appropriate to pressures and habitats that can be highly localised. Subdivisional metrics are aggregated by a weighted average where those weights are given by the total surveyed biomass of relevant assemblage in each subdivision.

Assessment Method

The Typical Length (TyL) is the weighted geometric mean length of fish, with weights given by the standardised catch rate of individuals in an area and defined as follows:

$$TyL = \exp \left[\frac{\sum_{i=1}^N M_i \ln L_i}{\sum_{i=1}^N M_i} \right]$$

where M_i is the body mass (standardised to kilogrammes per unit area fished) of the i -th fish with length L_i (in units of centimetres) in a sample of N fish.

Data for this indicator come from scientific fisheries surveys, which ideally sample the entire fish community but in practice do not. The indicator requires that surveys are conducted at regular intervals (e.g., annually) in the same area with a standard fishing gear. Sufficiency of available sample sizes can be judged using re-sampling techniques (Shephard *et al.*, 2012, Lynam and Rossberg, 2017). The absolute biomass of individuals in length classes present in the environment is not recorded directly by surveys, rather observations are made from samples with detection error (including many false negatives). The detection error is further complicated by differing catchabilities over length classes and species such that the relative abundance between species and length classes observed is survey specific. Where available, catchability estimates can be used to attempt to correct for this component of the systematic measurement error (e.g., Fraser *et al.*, 2007; Walker *et al.*, 2017). However, such estimates are sparse in the scientific literature and prone to great uncertainty. Alternatively, model-based estimates of absolute species abundance can be used to rescale observed abundances for some species (entire fish communities are not usually modelled), but here model uncertainty is also great (ICES, 2014b). For simplicity, Typical Length is defined with reference to a particular sampling design with a varying limitation to the size range sampled by fishing gear. For each survey, this indicator is calculated for subdivisions that represent different habitats and communities, where possible. Although each survey may provide a slightly different perspective to the reality, the surveys themselves are standardised so that they can be assumed to provide a consistent representation of that perspective over time.

The data are collected under the national programmes and the Data Collection Framework (EC, 665/2008). Currently, the most important data sources for Typical Length are those groundfish surveys that are conducted through the International Council for the Exploration of the Sea (ICES). The International Bottom Trawl Survey (IBTS) programme in the Greater North Sea, Celtic Seas, and Bay of Biscay and Iberian Coast is particularly important since the otter trawl gear used is a general-purpose design aimed to catch both demersal and pelagic species. However, beam trawl surveys are more efficient at catching benthivorous species such as sole (**Figure a**) and **time series** of Typical Length from such surveys may be preferable should sufficient length sampling of fish be made. The two gears (otter and beam) can therefore be assumed to provide complementary perspectives of the fish community.

Figure a: Common sole (*Solea solea*) (© Hans Hillewaert)

Data Used and Quality Assurance

The assessment draws on raw data from the ICES database of groundfish surveys (DATRAS, www.ices.dk/marine-data/data-portals/Pages/DATRAS.aspx). These data have been quality controlled by OSPAR as part of this assessment process to generate a data product for assessment purposes. Time series of Typical Length for fish and elasmobranchs are derived from each available groundfish survey, where the community is separated into demersal and pelagic habitat-based feeding assemblages.

Time series of Typical Length for demersal assemblages were determined for multiple surveys carried out across four OSPAR Regions: the Greater North Sea, Celtic Seas, Bay of Biscay and Iberian Coast, and Wider Atlantic (**Table a**). Ecological subdivisions were determined for the Greater North Sea using a simplification of those strata proposed by the EU financed project Towards a Joint Monitoring Programme for the North Sea and Celtic Sea (JMP NS/CS) that took place in 2013, and building upon work in the EU VECTORS project (Vectors of Change in European Marine Ecosystems and their Environmental and Socio-Economic Impacts) that examined the significant changes taking place in European seas, their causes, and the impacts they will have on society. In other OSPAR Regions, the strata from the survey design were considered appropriate to represent the ecological subdivisions.

Standard data collected on these surveys consists of numbers of each species of fish sampled in each trawl haul, measured to defined length categories (i.e., so a fish with a recorded length of 14 cm would be between 14.0 cm and 14.9 cm in length). By dividing species and size-specific catch numbers-at-length by the area swept by the trawl on each sampling occasion, these catch data are converted to standardised estimates of fish density-at-length, by species, at each sampling location (i.e., trawl haul). However, the indicator is based on biomass rather than abundance, so these abundance densities have to be converted to biomass density data by applying species weight (w) at length relationships (of the form $w = aL^b$, where a and b are species-specific parameters). Density estimates per length category per species based on biomass (kg per km²) are referred to below as catch-per-unit-area (CPUA).

These trawl-sample density-at-length estimates are averaged retaining year, species and length category information across all trawl samples within each sampling stratum (i.e., survey specific strata following the survey design, which is a rectangular grid in the Greater North Sea and generally depth-based strata elsewhere).

¹Survey acronym convention: first two to four capitalised letters indicate the European Union Marine Strategy Framework Directive (MSFD) sub-region (BBIC: Bay of Biscay and Iberian Coast; CS: Celtic Seas; GNS: Greater North Sea; WA: Wider Atlantic). Next capitalised and lower case letters signify the country involved (Spa: Spain; Por: Portugal; Fra: France; Eng: England; Bel: Belgium; Ire: Republic of Ireland; NIr: Northern Ireland; Sco: Scotland; Ger: Germany; Int: International; Net: The Netherlands).

International refers to the two international groundfish surveys carried out in the Greater North Sea under the auspices of ICES. In the Bay of Biscay and Iberian Coast sub-region, Spanish surveys are further delimited by (n) for surveys operating in the northern Iberian coast area and (s) for surveys operating in the southern Iberian coast area).

Next two capitalised letters indicate the type of survey (OT: otter trawl; BT: beam trawl). Final number indicates the season in which the survey is primarily undertaken (1: January to March; 3: July to September; 4: October to December).

²This is a single survey that operates across both the Celtic Seas and the Bay of Biscay and Iberian Coast sub-regions, from the southern coast of the Republic of Ireland and down the western Atlantic coast of France. For assessment purposes this single survey was split into its two sub-regional components.

Data Treatment

Surveys with rectangular sampling grids (GNSIntOT1, GNSIntOT3, GNSNetBT3, GNSGerBT3, GNSBelBT3, GNSEngBT3, GNSFraOT4)

Catch per unit swept area (CPUA) data (kg / km²) from multiple hauls are averaged by species for each rectangular grid cell using. In the **Greater North Sea** these are ICES statistical rectangles, in the eastern English Channel a mini-grid (0.25° by 0.25°) is used by GNSFraOT4. The resulting rectangle-based CPUA estimates are multiplied by the area (km²) of their rectangles (using a Lambert equal area projection) to give species biomass-at-length (now measured in kg per rectangle). Subdivisional strata level (not GNSFraOT4) estimates of biomass-at-length are given by the sum of the rectangle-based biomass-at-length estimates and corrected by a scaling factor = 1 / (proportion of the area of subdivision monitored in the survey year) (units are now tonnes per subdivision). The scaling factor correction ensures that the weighting of the strata relative to each other in each year is not altered by the sampling levels. Subdivisional estimates of Typical Length are calculated at this point for investigating local responses of each assemblage.

Regional estimates of biomass-at-length are estimated from the sum of subdivisions (or in the case of GNSFraOT4 by the rectangle-based estimates). Typical Length is calculated from these data to give a survey level assessment within each region.

Surveys with Irregular Depth Banded Strata (i.e., all surveys other than those with Rectangular Sampling Grids)

Catch-per-unit-area (CPUA) data (kg/km²) from multiple hauls are averaged by species for each survey strata. Subdivisional estimates of biomass-at-length are subsequently given by CPUA multiplied by area of the survey strata (km², using a Lambert equal area projection). Subdivisional estimates of Typical Length represent the local status of the fish community.

Regional estimates of biomass-at-length are estimated from the sum of subdivisions. The regional assessment of Typical Length is thus based on these summed subdivisional estimates.

Overall Assessment Basis

Where multiple surveys were available for assessment, key surveys were prioritised for assessment given the length of time series available and spatial coverage. If these measures were equal between surveys, then whichever surveyed the greatest biomass by assemblage was selected for indicator assessment. The following surveys were considered key:

Greater North Sea

GNSIntOT1 was selected as the key survey (preferred) for the **Greater North Sea**, given that it is the longest survey with the best spatial coverage. For the eastern English Channel, GNSEngBT3 was preferred given more consistent sampling here than GNSIntOT1 and GNSFraOT4.

Celtic Seas

CSScoOT1 was preferred over CSScoOT4 and CSIreOT4 due to length of time series. CSIreOT4 was preferred for subdivisions to the west of Ireland and in the northern Celtic Seas, but not in the north where there was overlap with CSScoOT1. CSFraOT4 was preferred in subdivisions of the Celtic Seas, except where overlap occurred with CSIreOT4. CSEngBT3 was preferred for the Irish Sea over CSNIrOT1 and CSNIrOT4 given the greater length of the survey.

Bay of Biscay and Iberian Coast

BBICsSpaOT1 was preferred over BBICsSpaOT4 given the length of the survey. CSBBFraOT4, BBICPorOT4 and BBICnSpaOT4 did not overlap with any other surveys. BBICFraOT4 was preferred over BBICFraBT4 due to length of survey.

Time-Series Assessment

The long-term trend in each time series (subdivision and survey level) was modelled through the application of a LOESS smoother (i.e., locally weighted scatterplot smoothing) with a simple 'fixed span' of one decade.

Breakpoint analyses uses data to define stable underlying periods (see Probst and Stelzenmüller, 2015). The method makes it possible to say whether there is a significant change in the time series state over time, namely whether the recent period is not significantly different from the historically observed period. The method avoids the arbitrary choice of reference periods for assessment (i.e., how many years to use to calculate an average) which can lead to subjective assessments. The shorter the period chosen, the more likely it is that noise in the data or natural fluctuations in the system are being compared against each other. However, too long a period and it could be that actual changes in state are averaged out. The minimum detectable period is defined in this analysis as six years and is assumed to be appropriate to capture the response of the fish community as opposed to noise (note that in the IA2017 assessment the minimum period was set as three years). The analysis uses two statistical approaches: First applying the 'supremum F test' to establish whether a non-stationary time series or a constant period for the entire time series is more suitable. If the former, then breakpoint analysis is applied to find periods of at least six years duration.

Populations should have a size structure indicative of sustainable populations and should occur at levels that ensure long-term sustainability in line with prevailing conditions. There should be no significant adverse change in the structure or function of fish assemblages due to human activities. The current assessment uses a time-series approach to identify long-term changes in state and further investigation is required to identify if reductions in the size structure of assemblages is due to human activities, food web interactions or prevailing climatic conditions. Analytical baselines are not currently available to determine assessment thresholds in terms of size-structure associated with healthy and sustainably fished assemblages. Nevertheless, fishing at Maximum Sustainable Yield in the North Sea has been shown to lead to gradual recovery in the indicator from current levels under currently prevailing conditions (Spence *et al.*, 2021). Despite the lack of an agreed outcome for a healthy ecosystem, a lower limit can be defined based on the lowest level of the indicator observed previously. If the most recent stable period is below all previous stable states (i.e., the indicator is at the minimum observed level and the ecosystem is more dominated by small individuals than ever observed previously) the indicator cannot be said to have achieved the threshold for 'no adverse change'. Therefore, an indicator outcome at the lowest stable state is defined as not-achieved. If the indicator has increased relative to previous periods or has not been observed to decline in the long-term the threshold 'no adverse change' is defined here as achieved.

Results (brief)*Greater North Sea*

Mixed results in TyL were evident across the eastern English Channel. Long-term change in the longest survey (GNSEngBT3 since 1990) were evident in the UK coastal area (increase since 1997) and in the French coastal area (decrease since 2014) (Figure 2 and Figure 3). However, a strong increasing trend in the subdivision overall was apparent in GNSFraOT4 (since 1998), while the more recent GNSIntOT1 (from 2007) was variable (Figure 3 and Figure 4).

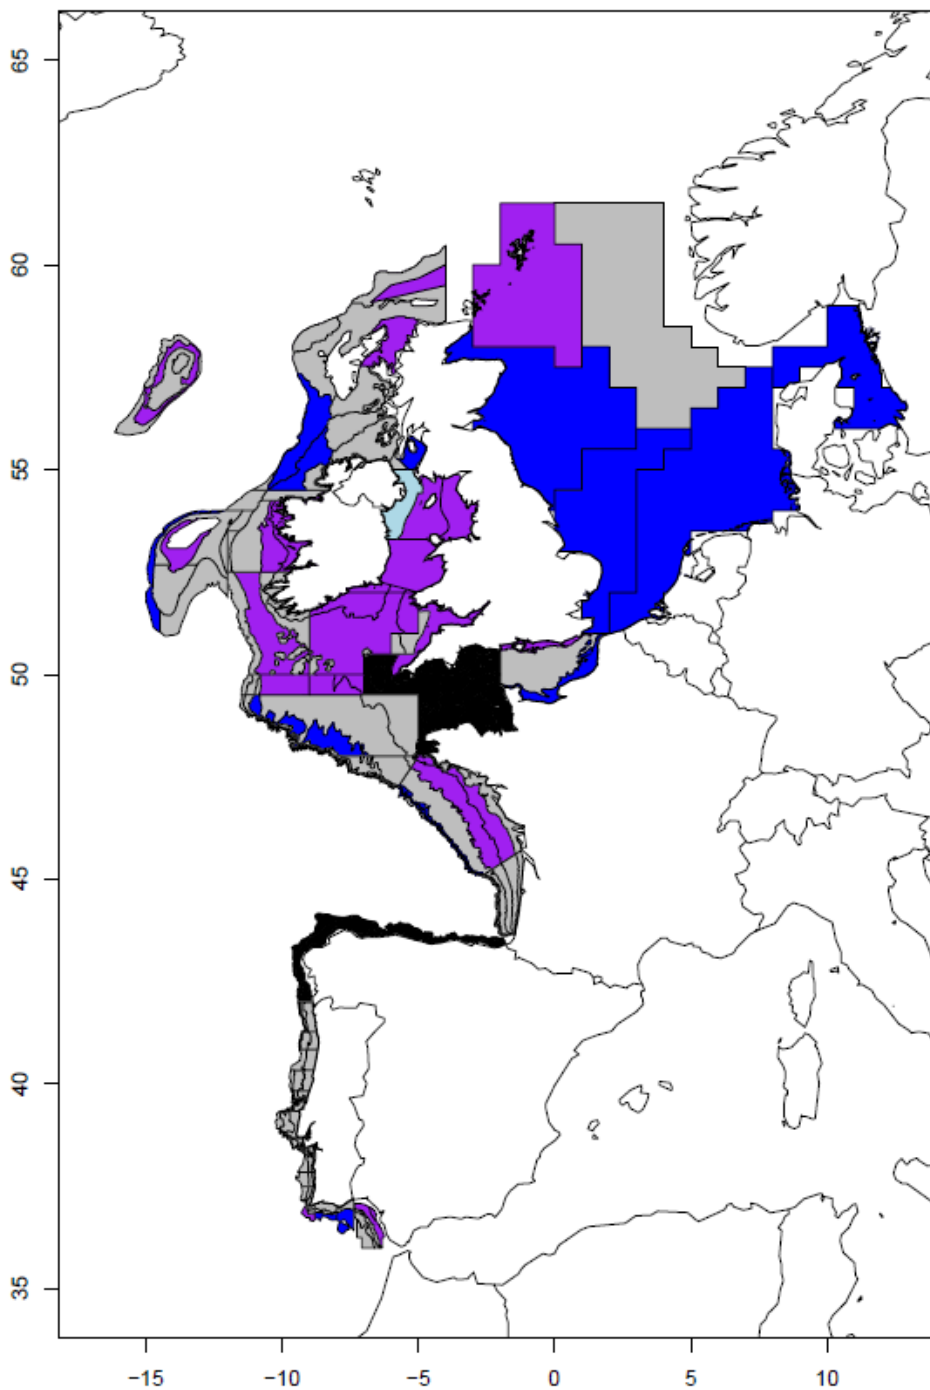

Figure 2: Spatial pattern in outcome of Typical Length indicator by subdivision for preferred surveys by Region. Purple colouring means long-term increase evident; dark blue shows decrease to minimum level; light blue shows decrease to low but not minimum level. Grey areas show areas with no long-term change evident and black area show surveys that are too short to detect long term change.

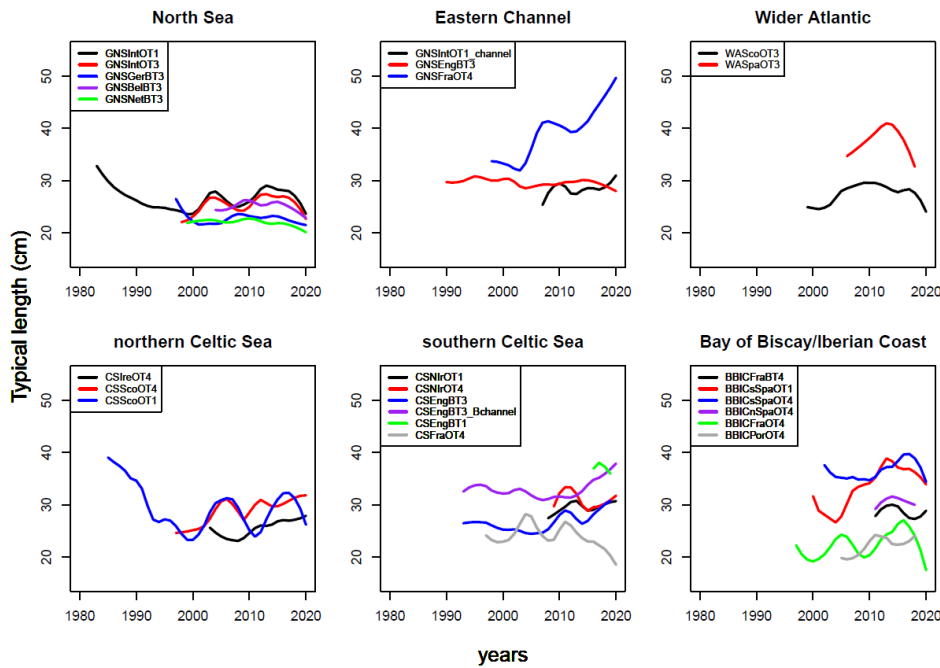

Figure 3: Time-series of Typical Length by survey, showing LOESS smoothed patterns, where overlapping surveys within Regions are grouped.

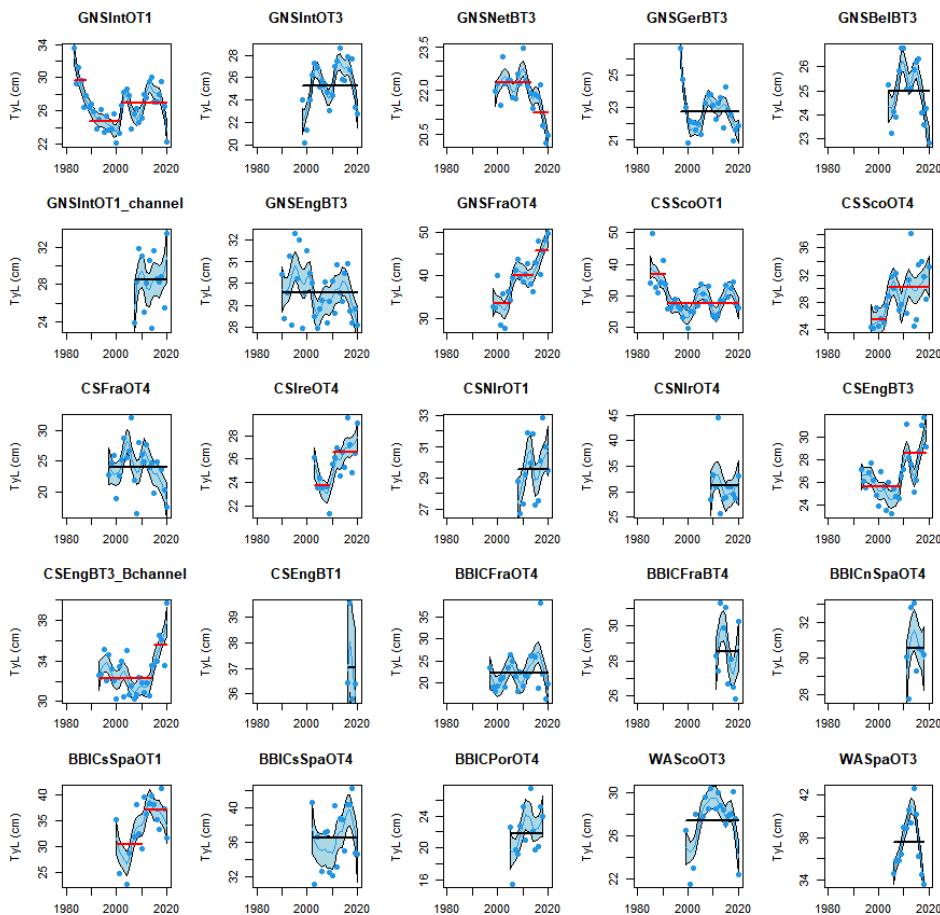

Figure 4: Time-series of Typical Length by survey showing data points, LOESS smoothed patterns and stable periods (black if constant over period assessed and red if a breakpoint is detected).

In the North Sea (including Kattegat), the longest running survey, i.e., GNSIntOT1, shows a long-term decrease to minimum levels during the 1990s prior to the start of the GNSIntOT3 survey and the beam trawl

surveys (**Figure 2** and **Figure 4**). A partial recovery from the minimum level is evident in GNSIntOT1 from the early 2000s, but this and the shorter time-series derived by GNSIntOT3 (from 1998) have been variable with no clear trend overall since then. The following overall patterns are apparent in the indicator of the North Sea: a decrease that was driven by change prior to 1990 in each subdivision (**Figure 5**), followed by a recovery in the two northern-most areas during the 2000s and a variable pattern with no clear trend in the 2010s.

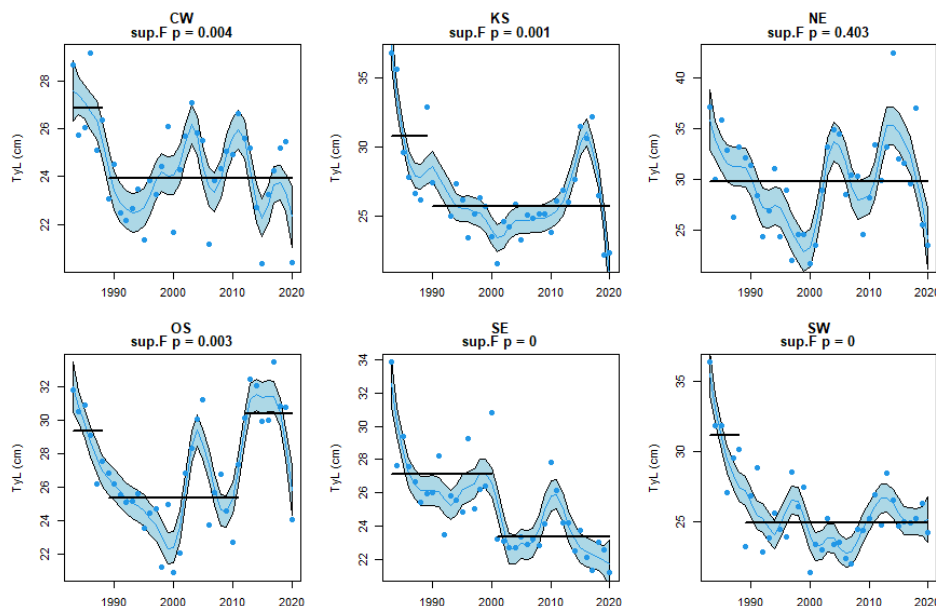

Figure 5: Subdivisional change within the North Sea (GNSIntOT1), where CW is central-west, KS is Kattegat-Skagerrak, NE is northeast, OS is Orkney-Shetland, SE is south-east and SW is south-west.

In the more recent beam trawl data for the central and southern North Sea, a decrease overall in 2005 (**Figure 4**) was found in GNSNetBT3 (due to change in the central areas, **Figure 6**) and in the south-eastern North Sea in GNSBelBT3, **Figure 7**.

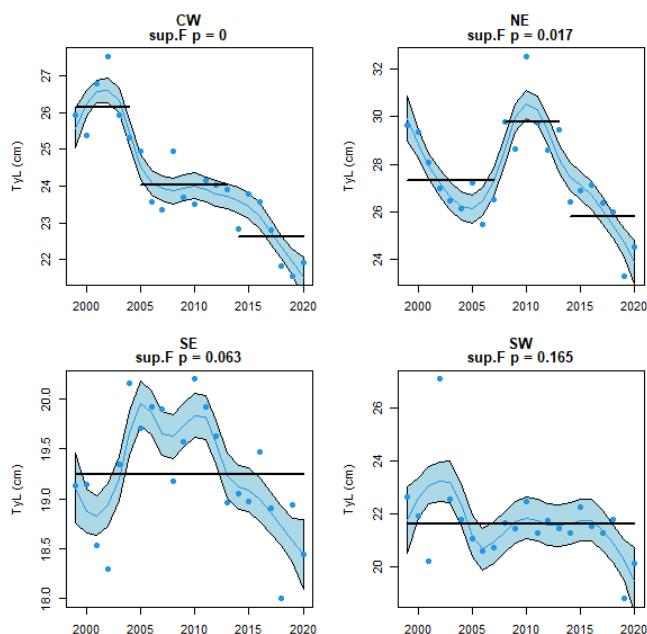

Figure 6: Subdivisional change within the North Sea (GNSNetBT3)

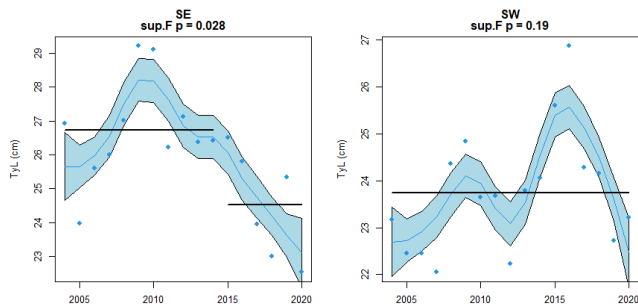

Figure 7: Subdivisional change within the North Sea (GNSBelBT3)

Celtic Seas

A mix of outcomes (increases, decreases and no change) were evident in the Celtic Seas Region (Figure 2). Overall increases were found in the Irish Sea (CSEngBT3) and Bristol Channel (CSEngBT3_Bchannel) and much of the Celtic Seas south of Ireland (CSIreOT4) (Figure 2, Figure 3 and Figure 4). However, to the south of the Region decreases were found for the deep waters at the edge of the shelf (CSFraOT4, Figure 2).

One survey, CSScoOT1, demonstrated an overall decrease in the area west of Scotland (Figure 3 and Figure 4). However, the shorter CSScoOT4 indicated signs of recovery since 2005 (Figure 3 and Figure 4). Within CSScoOT1, a small subdivision to the north of Scotland (Figure 2) was found to have increased in Typical Length during the mid-2000s as had the indicator for The Minch waters between mainland Scotland and the northern Hebrides (Figure 2). Nevertheless, the Clyde subdivision to the south-west of Scotland and the deep waters at the shelf edge remain at low values relative to the 1980s (Figure 2).

Bay of Biscay and Iberian coast

In the Bay of Biscay and Iberian Coast, five surveys showed no change overall and one, BBICSpaOT1, demonstrated an increase in southern areas of the Iberian Coast (Figure 2). Although there is no pattern overall in the Portuguese waters, there is evidence of a decrease in two southern coast subdivisions in BBICPorOT4 and an increase in one. In the northern Bay of Biscay, there is no pattern overall but two subdivisions on the shelf are increasing while TyL at the shelf edge is decreasing.

Wider Atlantic

No change overall was evident

Conclusion (brief)

There is no consistent pattern across the whole OSPAR Maritime Area.

Increases were found in the Irish Sea overall, Bristol Channel, part of Porcupine Bank, the a small subdivision to the north of Scotland and the northern Isles (Orkney and Shetland) area within the North Sea, parts of the northern Bay of Biscay and the northern Celtic Sea.

Decreases to minimum values were found in the central and southern North Sea and Kattegat and parts of the western edge of the shelf, the Clyde area and to the south of Portugal and part of the northern French coast.

Knowledge Gaps (brief)

Further work is required to evaluate appropriate baselines and assessment values for this indicator. This is necessary because any historical baseline for the fish and elasmobranch community is likely to represent an impacted state. Assessment values should preferably be identified through multi-species modelling.
